10 july 2026

1. Introduction

This report covers a basic Python program that takes input from the user and displays a personalised message using f-strings. It also shows how to convert input into a number so it can be used in a calculation.

2. Program — User Input and f-strings

The program asks the user for their name, age and city, calculates what their age will be next year, and then prints four formatted messages.

2.1 Code

```
name = input("Enter your name: ")
age = int(input("Enter your age: "))
city = input("Enter your city: ")
next_age = age + 1
print(f"Hello {name}!")
print(f"You are {age} years old.")
print(f"You live in {city}.")
print(f"Next year, you will be {next_age} years old.")
```

2.2 Sample Output

```
Enter your name: Daim
Enter your age: 20
Enter your city: Haripur
Hello Daim!
You are 20 years old.
You live in Haripur.
Next year, you will be 21 years old.
```

3. Explanation

The program uses three key ideas:

- `input()` reads what the user types and returns it as a string (text).
- `int()` converts the age text into a whole number, so 1 can be added to it (`next_age = age + 1`).
- f-strings (`f"...{variable}..."`) insert the variable values directly inside the printed messages.

Because age is converted with `int()`, the program can correctly calculate next year's age; without `int()` the value would stay text and the addition would fail.

4. Conclusion

This program practised taking user input, converting data types with `int()`, performing a simple calculation, and formatting output with f-strings. The program ran successfully and produced the expected personalised messages.
